Dataset Description

This dataset is from a manipulative experiment investigating the independent and combined effects of priority effects and habitat complexity on the strength of intraspecific competitive interactions among recently settled individuals of a coral reef fish (Thalassoma quinquevittatum: Labridae). This research was conducted in 2008 at the Gump Biological Research Station, Moorea, French Polynesia in the northern lagoon (17 30' S, 149 50' W).

This file describes the size distribution of Pocillopora colonies used in the experiment. For additional data, please see files listed in Related Datasets.

Methods & Sampling

This dataset describes the size distribution of *Pocillopora* colonies used in the experiment.

We examined the effects of habitat complexity and timing of arrival in the context of the survival of focal *Thalassoma quinquevittatum* settlers. The study was conducted in the northern lagoon of Moorea between April and June 2008. We used an array of 30 isolated live-coral patch reefs separated by *10 m in water 2–4 m deep. Reefs were located within a sand-flat, separated from each other, and from nearby natural reefs, by a minimum of 15 m. We constructed reefs to minimize habitat variation by standardizing size, rugosity, and water depth. Each reef consisted of a base of live *Porites lobata* coral with an average area of 2.23 m2 (SD = 0.56), and a mean height of 0.59 m (SD = 0.10). We controlled habitat complexity by manipulating the availability of the branching coral *Pocillopora verrucosa*. This was achieved by drilling holes into the upper surface of patch reefs. Into these holes, we inserted stainless steel pins attached to *P. verrucosa* colonies with Z-Spar Splash Zone Compound (Kopcoat, Pittsburgh, PA, USA). Mean colony surface area was 0.2 m^2 (SD = 0.07). We crossed the availability of *P. verrucosa* (two levels: two, or four colonies) with the presence of three tagged *T. quinquevittatum* competitors (three levels: absent, introduced simultaneously with (0 days), or 5 days earlier than the focal individuals). To each reef, we simulated settlement by introducing three tagged *T. quinquevittatum* focal individuals. Thus, our design had six treatments: (1) focal individuals without competitors, with two *P. verrucosa* colonies; (2) focal individuals and competitors introduced simultaneously, with two *P. verrucosa* colonies; (3) focal individuals with competitors introduced 5 days previously, with two *P. verrucosa* colonies; (4) focal individuals without competitors, with four *P. verrucosa* colonies; (5) focal individuals and competitors introduced simultaneously, with four *P. verrucosa* colonies; and (6) focal individuals with competitors introduced 5 days previously, with four *P. verrucosa* colonies. We ran the experiment in two temporal blocks (17–23 April and 1–7 May 2008), yielding ten replicates (five in each temporal block) for each of the six treatments. We surveyed reefs twice daily (approximately 0800 and 1600 hours) for 5 days after the introduction of focal individuals.

Data Processing Description

poc_area_m2 was calculated as the total surface area of a rectangle using over_top_length, over_top_width, and max_height.

BCO-DMO Processing:

- added conventional header with dataset name, PI name, version date
- modified parameter names to conform with BCO-DMO naming conventions

General

Parameters

Parameter	Description	Units
colony	unique identifier for each Pocillopora colony	unitless
over_top_length	distance in meters of the over the top length of the Pocillopora colony	meters (m)
over_top_width	distance in meters of the over the top width of the Pocillopora colony	meters (m)
max_height	distance in meters of the maximum height of the Pocillopora colony	meters (m)
poc_area_m2	surface area of the Pocillopora colony in square meters (calculated as the total surface area of a rectangle using over_top_length over_top_width and max_height.)	square meters (m2)

Project Information

Cryptic density dependence: the effects of spatial, ontogenetic, and individual variation in reef fish (CDD_in_Reef_Fish)

Coverage: Moorea, French Polynesia (-17.48, -149.82)

Description from NSF award abstract:
Ecologists have long been interested in the factors that drive spatial and temporal variability in population density and structure. In marine reef systems, attention has focused on the role of settlement-the transition of pelagic larvae to a benthic stage-and on density-dependent processes affecting recently settled juveniles. Recent data suggest that co-variance in settlement and subsequent density-dependent survival can obscure the patterns of density dependence at larger scales, a phenomenon called cryptic density dependence. This research will explore the mechanisms that underlie the spatial covariance of settlement and site quality - a process that has received little attention in the standard paradigm. These mechanistic studies of cryptic density dependence will facilitate the development of new frameworks for fish population dynamics that incorporate larval ecology, habitat quality, density dependence, life history, and the patterns and implications of spatial covariance among these factors. More generally, the work provides a specific empirical context, and a general theoretical treatment, of cryptic heterogeneity (hidden individual variation in demographic rates).

Note: Drs. Craig W. Osenberg and Ben Bolker were at the University of Florida at the time the NSF award was granted. Dr. Osenberg moved to the University of Georgia during the summer of 2014 (current contact information). Dr. Bolker moved to McMaster University in 2010 (current contact information).
